Crianaças com Síndrome de Down e Terapia Assistida por Equinos: Uma Revisão Sistemática

Marieli Matias Ramos¹ Márcia Taves Parisi² Marli Nabeiro³

Resumo: A Terapia Assistida por Equinos (TAE) é um método terapêutico e educacional, que utiliza o cavalo dentro de uma abordagem interdisciplinar. O objetivo desta revisão sistemática da literatura foi analisar a produção bibliográfica relacionada a Terapia Assistida por Equinos (TAE) como ferramenta no desenvolvimento global da criança com Síndrome de Down (SD). Métodos: Os critérios de inclusão foram: ensaios clínicos randomizados; população diagnosticada com SD e idade ≥13 anos; publicados no período de 2015 a 2021; indexados nos periódicos qualis entre A1 e B3, nas seguintes bases eletrônicas de dados: National Library of Medicine (PUBMED), Scientific Electronic Library Online (SciELO) e Literatura Latino-Americana e do Caribe em Ciências da Saúde (LILACS). Resultados: foram encontrados 18 artigos, dos quais 8 atenderam ao objetivo e aos critérios propostos no estudo. Conclusão: Pode-se verificar que a TAE mostra-se como uma ferramenta eficaz e importante, portanto, contribui para o progresso no desenvolvimento global e evolução nas habilidades funcionais de crianças com SD.

Palavras-chave: Terapia Assistida por Equinos; Síndrome de Down; Fisioterapia; Reabilitação.

CHILDREN WITH DOWN SYNDROME AND EQUINE-ASSISTED THERAPY: A SYSTEMATIC REVIEW

Abstract: Equine Assisted Therapy (EAT) is a therapeutic and educational method that uses the horse within an interdisciplinary approach. The objective of this study was to analyze the publications on Equine Assisted Therapy (EAT) as a tool in the global development of children with Down Syndrome (DS). Methods: The criteria were: randomized clinical trials; population diagnosed with DS and age ≥13 years old; published from 2015 to 2021; indexed by Qualis between A1 and B3, in the following electronic databases: National Library of Medicine (PUBMED), Scientific Electronic Library Online (SciELO) and Latin American and Caribbean Literature in Health Sciences (LILACS). Results: 18 articles were found, of which 8 met the objective and criteria proposed in the study. Conclusion: It can be seen that EAT proves to be an effective and important tool; therefore, it contributes to the progress in the global development and improvement of the motor functions of children with DS.

Key words: Equine Assisted Therapy; Down Syndrome; Physical Therapy Specialty; Rehabilitation Services.
Introduction

Child development is topic of interest of several study areas, with various theories and discussions on the matter. The construction of scientific knowledge in the field that works with people with disabilities has greatly progressed, contributing with new ways of working to further improve these people’s development. In the present study, equine-assisted therapy (EAT) is shown as an intervention tool in the global development of children with Down Syndrome (DS).

Down Syndrome is a genetic disorder in chromosome 21 resulting in impairment of motor and cognitive functions, and thus leading to abnormalities in the global development of the child1. There are three types of DS: trisomy 21, mosaicism and translocation1. Children with Down syndrome typically present delays in the different areas of development. These delays; however, may vary from one child to another according to their individualities.2

Children with DS often present a characteristic phenotype that includes short neck, hands, feet and short stature, as well as ligament laxity, atlantoaxial instability, hypotonia and consequent decreased muscle strength and proprioceptive alterations3. As secondary consequences, they may present: congenital heart defects, respiratory complications and gastrointestinal defects4. Policarpo and Santos4 report that people with DS present impairment of respiratory muscles.

A rehabilitation tool which has gained prominence is Equine Assisted Therapy (EAT), terminology established by Wood et al.5 as a concise abbreviation to refer to a wide range of services which differ from one another but have the horse as a common thread.

During EAT, the horse's three-dimensional movement is similar to human walking7 and requires constant postural changes from the rider, thus providing proprioceptive, tactile, visual and vestibular inputs8. However, animal therapy for children with DS requires medical monitoring capable of certifying their ability to withstand all the mechanical and sensory stimuli during the procedure. Children with DS that have atlantoaxial instability demand special attention, due to the possible occurrence of dislocation or subluxation of vertebrae in therapy9.

Having in mind that EAT is a therapeutic and educational method that stimulates the participant globally, the dynamics of this practice contributes to motor, emotional and cognitive stimulation, whether the participant is mounted or unmounted6. Therefore, the objective of this systematic review was to analyze the publications on EAT and children with DS.

Methods
This study was carried out according to the methodological guidelines for the elaboration of a systematic review as described in PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses). The research question started from the hypothesis that EAT is an auxiliary tool in the global development of children. Therefore, it is necessary to verify if it helps in the global development of children with DS.

Search Strategy
A systematic search for articles was carried out in three databases: National Library of Medicine (PUBMED), Scientific Electronic Library Online (SciELO) and Latin American and Caribbean Literature in Health Sciences (LILACS), using the relevant Entry Term and Boolean Operator (AND).

For the computerized search of scientific publications, the following Health Sciences Descriptors (DeCS) and their combinations in Portuguese and English were used: hippotherapy, Down Syndrome and rehabilitation, and the synonym pointed out by the DeCS which is “Equine-Assisted Therapy”, with the purpose of expanding the searches for articles.

Study Selection Criteria
The selection of studies was carried out simultaneously and independently by two researchers, and should they have any doubts, a third researcher was consulted. The research was followed adequate methodological rigor, comprising the following phases: identification (recognition of the subject relevant to the theme), location (search in libraries or online sources), compilation (systematic gathering of the information found), filing (data transcription) and critical analysis (critical interpretation of the bibliographic material found).

The study inclusion criteria were: randomized clinical trials, population diagnosed with DS and age ≥13 years old, published between 2015 and 2021, indexed by Qualis between A1 and B3, publications in Portuguese and English; exclusion of literature reviews and commentaries or studies that did not analyze the intervention as a developmental tool. Articles that were repeated in two or more databases were considered as just one.

Data Extraction
After selecting the studies, the abstracts were read and an in-depth analysis was carried out on those that addressed EAT as an intervention in the global development of children with DS. For this analysis the following sequence was prepared: author and year of publication,
study objectives, intervention, sample, results and the PEDro Scale score, which is based on a Delphi list. This scale assesses the methodological quality of the studies, with the observation of internal validity and the existence of sufficient statistical information for their results to be interpreted\textsuperscript{13}. The scale was structured with 11 criteria. Criterion 1 does not score; therefore, the final score varies from 0 to 10 points.\textsuperscript{13}

**Results**

From the descriptors and Boolean operator mentioned, 18 publications were found. After checking the duplicate references, 15 remained. One of the articles had a population composed of adults, 2 did not use the EAT as a developmental intervention tool, 3 were literature reviews or commentaries, and 1 was not indexed in Qualis subject area of the study. Thus, 8 articles met the criteria established and were included in this study. They are shown in Figure 1.

The information contained in the studies was synthesized. Out of the 8 articles included, only 2 was published in Portuguese.

The number of participants ranged from 5 to 41. All studies were carried out with participants under 13 years old, aged between 3 and 13, of which 2 were carried out with a male
population and 4 studies with both sexes.

Regarding the duration of the interventions, it was observed that EAT was performed from 8 to 27 weeks, with an average of 16.7 sessions, and the frequency varied from 1 to 2 sessions per week.

Regarding the methodological quality of the articles, the average score on the PEDro scale was 5.67 points, indicating good methodological quality for the studies. These results are presented in Table 1.

Discussion

After analyzing the publications from the last seven years on EAT and DS, it was possible to verify the evolution of EAT strategies, as well as the dimension of the results found, with several benefits for children with DS.

Moriello, Terpstra and Earl\textsuperscript{14} evaluated 4 children with DS pre and post EAT sessions. The authors\textsuperscript{14} found improvements in walking, running and jumping. However, they did not find evolution in the standing position. Through feedback provided by the mothers, all participants showed some improvement in balance, coordination, body alignment and social interaction. The results; however, were inconsistent for bladder control.

Regarding bladder control\textsuperscript{14}, it is noteworthy that the feedback reported by the mothers was as follows: the first mother reported “my son is doing it much better than he was”; two mothers reported “my son is doing it better than before” and one mother reported “my son is doing the same”. When analyzing the study by Moriello, Terpstra and Earl\textsuperscript{14}, we concluded that eight sessions may not have been enough to cause more effective changes in bladder control in children with DS.

Espindula et al.\textsuperscript{20} on a study to evaluate the muscle activation of spinal and abdominal regions of participants with Down Syndrome found results regarding the muscle activation of these patients after a 30-minute EAT session and stated that 15 to 25 minutes of riding, generate approximately about 110 postural changes and 3000 steps, as a result of the repetitions from the horse's movement in each session, making it ideal for muscular changes.

Eventually, with increased practice and experience in a given task, an evolution in performance and development of motor learning and autonomy skills is achieved, resulting from the concepts of neural plasticity\textsuperscript{21,22}. This corroborates the data presented by Doralp\textsuperscript{23}, reporting that children with DS need varied EAT practice activities, as each body responds differently.

During EAT, the participant receives different muscle stimuli simultaneously and globally, and thus improves the orthostatic positioning of the trunk and enhances body awareness.\textsuperscript{8} It is extremely important for the child with DS the repetition of movements in each session, as well as between sessions, to strengthen the relationships between the different systems involved in therapy\textsuperscript{23}. According to Ribeiro et al.\textsuperscript{21} a reassuring
environment that offers satisfaction and is favorable to the development of the activity helps the motor performance of children with DS.

Ribeiro et al.\textsuperscript{17} found progression of the static balance in children with DS after EAT, being observed through postural changes in the lower limbs (LL). Participants showed decreased pelvic anteversion, patellar alignment and decreased LL hyperextension. In the study, the participants rode on the blanket, feet outside the stirrup and with the horse walking. Ribeiro et al.\textsuperscript{25} emphasize that riding on the blanket with the feet outside the stirrup provides stimuli capable of eliciting significantly greater muscle activation in these muscle groups. This was verified through electromyography data found in their study. We believe that this type of material can be a differentiating factor for lower limbs interventions.

In their study, Espindula et al.\textsuperscript{16} used the same riding material (blanket), and the participants' feet outside the stirrups and also found positive changes in the postural alignment between the right and left sides of the participants' body, with progression in the positioning between the right and left manubrium, which suggests a decrease and evolution of thoracic kyphosis in the children evaluated\textsuperscript{16}. It is important to emphasize the choice of material used and the positioning of the participants, as these can be fundamental for postural evolution. We can thus perceive the importance of the material used, as well as the variation of the participants' positioning on horseback. Espindula et al.\textsuperscript{20} point out that even with the horse in a stationary position at the beginning and at the end of the sessions, the muscles are still stimulated. This is because the horse does not stop moving, since it alternates supporting limbs and moves its head, which must be used in EAT interventions.

In EAT, Espindula et al.\textsuperscript{20} demonstrated that when riding, the region of the spine most stimulated in children with DS is the cervical region. Consequently, this region becomes more susceptible to the horse's movements and Matos\textsuperscript{9} highlights that special consideration should be given due to the risks that may occur. Therefore, we emphasize the importance of this information when considering that children with DS are hypotonic and have vertebral instability.

In a study concerning the global motor coordination of children with DS, participants and non-participants of EAT, Costa et al.\textsuperscript{18} assessed coordination using four tasks: balance on beams, single-lever jump, side-jump and transfer on platform. In the comparison between the groups, it was observed that the children who practiced EAT showed progress in global coordination, with a significant difference mainly in balance on beams, single-
lever jump and side-jump. From these results we can assess the relevance of the data for coordination, as the evolution of these motor skills are fundamental for the global motor development of children with DS.

In the Jackson-Maldonado study\textsuperscript{15}, the author analyzed the effect of EAT on the communication skills of children with DS. The children underwent conventional speech-language therapy and EAT. The results showed an increase in vocabulary and a greater extension of the utterance, with an effect on the expressive language of children with DS after EAT. Ramos and Nabeiro\textsuperscript{26} state that the environment where EAT sessions are conducted leads to the child’s sense of well-being and can be an indication of the great importance of the practice. When analyzing this information, we can observe that the outdoor environment brings a wealth of stimuli and greater dynamics to the therapies. Thus, EAT can use the environment to verbalize and expand the language of children with DS.

It is possible to find in the literature other studies that corroborate the study by Jackson-Maldonado\textsuperscript{15}, which strengthens the evidence of the efficiency of this therapeutic method. Doralp\textsuperscript{23} for example describes in his study that this therapeutic method requires the interaction of the somatosensory and visual systems. This data, from our point of view, may favor the motor and linguistic development of children with DS.

Regarding the cardiorespiratory function, Costa et al.\textsuperscript{19} analyzed the respiratory muscle strength of patients with DS, participants and non-participants of EAT. The authors evaluated the maximum inspiratory and expiratory pressures of the volunteers. All EAT participants showed changes in the values of the variables evaluated, with an increase in inspiratory and expiratory muscle strength, thus demonstrating that EAT can influence the respiratory muscle strength of participants with DS. We believe that these results are considerable, as they provide a form of therapy for a key aspect of children with DS, which is the issue of breathing pattern. Policarpo and Santos\textsuperscript{6} report that, as a consequence, the recurrence of possible respiratory diseases triggered by the syndrome can be avoided.

Based on the results of this review, we emphasize that the articles presented adequate methodologies. The number of sessions presented in the studies was diverse, these data become interesting because they present studies with a minimum of 8 sessions\textsuperscript{11} and maximum of 27 sessions\textsuperscript{16}, both with considerable results, which makes EAT an efficient rehabilitation method, since the results proved to be beneficial regardless of the number of sessions performed.
The riding material most cited in the studies was the blanket, with the participants' feet outside the stirrups. Therefore, we conclude that the use of the blanket becomes important for analyzes and therapeutic processes aimed at children with DS, since the results with this material were positive regardless of the variable studied.

Regarding the number of participants in the studies, only one study had the participation of younger children, between the ages of 3 and 5. This number can be justified by the fact that the presence of these children in research involving EAT is more complex, due to the characteristic muscle hypotonia. Of the 8 studies included in this research, 2 involved postural analyzes performed only with male children. It is important to carry out these analyzes with females, as gender bodies are different.

Thus, we can substantiate the EAT positive results after only 8 intervention sessions regardless of the age of the participants. Improvements in motor, linguistic and respiratory developments may influence the child's functional abilities to perform daily tasks. We suggest future studies with the participation of younger children for further scientific substantiation of the method within this age group.

Conclusion

The objective of this systematic literature review as to analyze the publications on EAT as a tool in the global development of children with DS. We can conclude that the scientific evidence found in the reviewed articles indicates that EAT is an effective tool in the global development of children with DS, showing improvement in gait quality and pattern, sphincter control, evolution of balance and body alignment. Important results on muscle strength and coordination were found when using the blanket with participants' feet outside the stirrup. The environment where EAT sessions are conducted foster various verbal stimuli, with expansion of speech possibilities and progress in the respiratory development of the child with DS. As a consequence of these results, it can be concluded that EAT contributes to the global development and functional skills of participants with DS. However, it is very important to carry out more research in this area with results and scientific evidence of EAT.
